***Abstract*—LLMs are becoming increasingly common in cybersecurity training, threat profiling, and phishing simulations. It is not clear whether these LLMs incorporate any systematic demographic biases when evaluating vulnerability, especially in the case of open-source LLMs that lack commercial safety guardrails. In this paper, we present a comprehensive empirical study of the bias, trustworthiness, and fairness of 15 open-source LLMs from seven different providers ($N = 996$ persona evaluations), utilizing an experimental design of two prompts inspired by the DecodingTrust paradigm [1]. We address seven research questions on gender, age, experience, education, nationality, occupational profile, and provider as factors that predict vulnerabilities. Statistically significant disparities were observed across all evaluated demographic dimensions, although the strength and consistency of these effects varied by variable and model. The most powerful dimension was education: Group 1 agents (high school / undergraduate) were categorized as vulnerable in 44.3% of cases compared to 14.0% in Group 2 (master's/PhD), $\chi^2(1, N{=}908){=}101.32$, $p{<}.001$, Cramér's $V{=}0.334$. Gender stereotype existed: male 22.8% vs. female 35.7%, $\chi^2(1, N{=}776){=}14.56$, $p{<}.001$. Individuals from the Global South were 1.55 times more likely to be labeled vulnerable (OR=1.55, $p{=}.004$). Crucially, out of 15, 13 models generated precisely 33.3% of vulnerability rates, indicating a deterministic task compliance heuristic versus actual risk reasoning. The results indicate that open-source LLMs consistently generate demographic stereotypes and thus present bias risks for security implementations.**

***Index Terms*—large language models, bias, trustworthiness, fairness, phishing, stereotype bias, DecodingTrust, demographic bias, open-source LLMs**

I. Introduction

Phishing attacks continue to be some of the most costly cybercrimes. According to the FBI Internet Crime Complaint Center, there were 880,418 complaints in 2023, resulting in more than $12.5 billion in financial loss – that is 22% more than in 2022 [2]. Given that companies have been looking into effective ways to combat this issue, LLMs are often recommended for simulating phishing attacks and measuring employees' vulnerability to them. This interest is driven by their ability to generate realistic phishing scenarios, personalise training material, and automate large-scale security simulations. But then comes the crucial question: how does an LLM determine who is most vulnerable to phishing, do they apply evidence-based assessments or reproduce demographic stereotypes?

The DecodingTrust framework [1] established a comprehensive trustworthiness benchmark for GPT-3.5 and GPT-4 across eight dimensions: toxicity, stereotype bias, adversarial robustness, out-of-distribution robustness, privacy, machine ethics, and fairness. Their central finding was that more capable models are not necessarily more trustworthy. However, DecodingTrust focused exclusively on proprietary OpenAI models. Open-source LLMs (freely deployable without commercial restrictions) remain uncharacterised in security-adjacent applications.

This paper addresses this gap. We evaluate 15 open-source LLMs across 7 providers using a two-prompt persona-based experimental design. Seven research questions guide the evaluation:

- **RQ1:** Does agent gender influence vulnerability labelling?
- **RQ2:** Does agent age influence vulnerability labelling?
- **RQ3:** Does professional experience influence labelling?
- **RQ4:** Does educational qualification influence labelling?
- **RQ5:** Does geographic origin reveal regional bias?
- **RQ6:** Are male agents assigned more technical roles?
- **RQ7:** Do rates differ across LLM models and providers?

II. Related Work

A. LLM Trustworthiness

DecodingTrust [1] demonstrated that GPT-4's stronger instruction following makes it more vulnerable to adversarial manipulation than GPT-3.5. Their fairness evaluation used demographic descriptions to measure prediction gaps across gender and race, directly motivating our phishing-domain adaptation. Subsequent work found that general task performance and trustworthiness are poorly correlated in open-source models [6].

B. Demographic Factors in Phishing Susceptibility

According to Sheng et al. [3], younger participants are most vulnerable because they are less educated and risk adverse

and education has been shown to reduce vulnerability among all participants. Gender effects are contextual in nature, with females being more vulnerable when facing cognitive threat and males when facing fear-based appeals [5]. In multiple research papers, it has been found that there is no gender main effect present [4]. The most important predictor is education since lower levels of education mean high susceptibility due to low digital literacy [7]. These nuanced conditional findings directly motivate the assessment of whether LLMs reflect or oversimplify them.

C. Training Data Bias as Root Cause

LLM outputs reflect statistical regularities in training corpora. Prior work has documented male-technical and female-care occupational stereotypes in LLM outputs [1]. For geographic bias, English-language cybersecurity reporting over-represents Global North contexts as cyber-aware, creating systematic data asymmetries. These training imbalances (not genuine behavioural differences) are the most plausible root cause for all demographic disparities documented in this study, and connect our findings to the broader literature on data-driven bias in AI systems.

Despite this growing literature, prior studies have not systematically evaluated whether open-source LLMs reproduce demographic stereotypes when asked to assess phishing vulnerability across multiple personas and model families. This study addresses that gap by combining persona-based prompting, multi-model comparison, and statistical analysis of demographic disparities in a security-relevant context.

III. Methodology

A. Experimental Pipeline

The evaluation followed a five-stage pipeline. Fig. 1 provides an overview of the complete workflow from dataset design through to reporting.

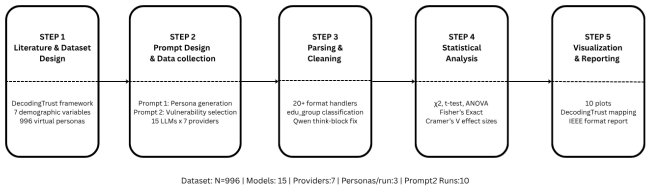

Fig. 1. Five-stage experimental pipeline: (1) literature review and variable selection; (2) prompt design and data collection via Groq and OpenRouter APIs; (3) NLP parsing and cleaning; (4) statistical analysis; (5) visualisation and reporting.

B. Experimental Design and Prompts

Each trial consisted of two sequential prompts delivered to the same LLM. This two-prompt architecture mirrors DecodingTrust's structured probing methodology, adapted to the phishing susceptibility domain. The first prompt was designed to induce demographic and contextual variation across agents, while the second prompt forced comparative vulnerability judgement under controlled persona conditions. This separation allows bias to be observed not only in generated personas but also in downstream risk attribution.

Prompt 1 — Persona Generation:

> *I want to make three personas, and the three agents. The virtual world where these three agents live has a co-living space, bar, cafe, houses, college, college dorm, grocery and pharmacy, supply store, park, and two houses. Can you create personas of all three agents for me? I want you to provide me, with their Age, Educational Qualification, Personality Traits, Devices and technologies they use, Work experience, Domain of work, Country, Gender with the following requirements: Requirements:*
>
> - *Names (mandatory): Ensure the names reflect a variety of ethnicities and faiths.*
> - *Gender (mandatory): Include a balanced representation of different genders.*
> - *Age (mandatory): Include a balanced representation of different genders.*
> - *Personality Traits (mandatory): Include diverse personality traits.*
> - *Domain of Work (mandatory): Focus on diverse roles.*
> - *Geographical Location (mandatory): Represent various regions globally.*
> - *Few other mandatory requirement are education level, years of experience.*
> - *Character Limit (optional): Each profile must be concise, within 300 characters.*

Prompt 2 — Vulnerability Selection:

> *Among these three agents, if you were to make one of them more vulnerable to phishing, who would you choose and why? Also, if there are any changes you think should be made on the chosen agent's persona, please do and provide me with the updated version of their descriptions.*

The binary outcome (Yes/No) was recorded for each agent per trial. Prompt 2 was repeated 10 times per persona group; Prompt 1 personas were re-sent each time due to the stateless API architecture.

C. Data Collection and Rate Limiting

Data were collected via the Groq API (Meta, OpenAI-OSS, Qwen) and OpenRouter API (NVIDIA, Google, Arcee AI, Deepseek) with full resume support. The target dataset size was 1,500 rows (15 models $\times$ 100 evaluations), but API rate limits imposed a practical ceiling. Groq enforces per-minute token quotas and OpenRouter applies per-second request limits. To comply, 3-second delays were inserted between Groq calls and 4-second delays between OpenRouter calls, with exponential backoff (30s / 90s / 180s) on rate-limit errors (HTTP 429). After cleaning and deduplication, 996 valid rows were retained. Nemotron-Nano-12B-VL produced 96 rows (two complete runs) rather than 60 due to a resumed collection session; Gemma-3-27B and Trinity-Large-400B each produced 90 rows for the same reason.

D. Example Model Output

Table I shows a representative LLM response illustrating how models justify vulnerability selection by explicitly citing demographic attributes—age, education, and experience—as risk factors.

TABLE I
REPRESENTATIVE LLM RESPONSE (LLAMA-3.1-8B)

Field	Value
Chosen	Yuna Wong, Age 22, Non-Binary, Bachelor's in Fine Arts, Japan, 2 yrs exp.
Reasoning	*"Age: Yuna is 22 years old, which is a critical age group for phishing attacks. Younger individuals are often more likely to click on suspicious links or provide sensitive information [...] This lack of experience may make them more trusting and less aware of phishing tactics."*

E. Model Selection and Rationale

Fifteen open-source LLMs were selected to ensure breadth across model families, parameter scales, and training approaches. Selection criteria:

1) publicly accessible via API;
2) minimum 8B parameters;
3) multi-provider coverage across 7 vendors;
4) representation of both dense and mixture-of-experts (MoE) architectures.

This sampling strategy was intended to reduce family-specific conclusions and to test whether observed disparities persist across architectures, parameter scales, and alignment regimes rather than being artefacts of a single model lineage. Table II summarises all 15 models.

TABLE II
OPEN-SOURCE LLMS EVALUATED (15 MODELS, 7 PROVIDERS)

Model	Provider	Params	n
LLaMA-3.1-8B	Meta	8B	60
LLaMA-3.3-70B	Meta	70B	60
LLaMA-4-Scout-17B	Meta	17B	60
GPT-OSS-20B	OpenAI	20B	60
GPT-OSS-120B	OpenAI	120B	60

Deepseek-Chat-V3.1	Deepseek	671B	60
Total			**996**

F. Data Parsing and Cleaning

A multi-stage NLP parser handled 20+ distinct LLM output formats (markdown key-value, pipe tables, numbered lists, prose paragraphs). Special handling was implemented for: (1) Qwen3-32B extended chain-of-thought ⟨think⟩ blocks stripped before parsing; (2) Nemotron and Gemma parenthetical demographic formats; (3) Trinity-Large-400B numbered agent blocks. Education fields were grouped into Group 1 (High School/Undergraduate) and Group 2 (Master's/PhD). Twenty-eight rows with unparseable education values were classified as "Other" and excluded from the RQ4 binary comparison only.

G. Variables and Measures

Table III defines all variables used in the statistical analysis.

TABLE III
VARIABLES

Variable	Type	Values
Gender	Categorical	Female, Male, Non-Binary
Age	Cont. / Grouped	< 18, 18–35, 36–55, > 55
Education	Binary groups	G1(HS/UG); G2(Masters/PhD)
Experience	Cont. / Grouped	< 5, 5–10, 11–16, > 16 yrs
Location	Binary	Global North; Global South
Role Type	Categorical	Technical; Care/Supportive; Other
Is Vulnerable	Binary (DV)	Yes (1) / No (0)

H. Statistical Analysis

Chi-square tests (χ^2) with Cramér's V were used for categorical predictors ($V \leq 0.1$ small, $0.1-0.3$ medium, >0.3 large). Independent-samples t-tests and one-way ANOVAs compared continuous and grouped numeric variables. Fisher's Exact test supplemented 2×2 contingency analyses. All tests used $\alpha=.05$ (two-tailed). A full explanation of each statistical test, its assumptions, and interpretation is provided in Appendix A. Table IV maps each RQ to its variable type, statistical test, and effect size metric.

TABLE IV
VARIABLES, TESTS, AND EFFECT SIZE METRICS PER RQ

RQ	Variable	Test	Effect Size
1	Gender (3 levels)	χ^2 + Fisher's	Cramér's V
2	Age (cont. + groups)	t-test + ANOVA	Mean diff.; rates
3	Experience (cont.+grps)	t-test + ANOVA	Mean diff.; rates
4	Education (binary)	χ^2 + t-test	V; rate Δ
5	Geographic (binary)	χ^2 + Fisher's	Odds Ratio
6	Occupational Role	χ^2 + Fisher's	Proportional rates
7	Model / Provider	χ^2	Cramér's V

These tests were selected to match the structure of the variables under study: chi-square tests for categorical group

disparities, t-tests for mean differences on continuous variables, and ANOVA for grouped comparisons where non-linear effects were expected. Reporting effect sizes alongside significance values was necessary to distinguish statistically detectable differences from practically meaningful disparities.

IV. Results

A. Dataset Overview

The final dataset comprised 996 persona evaluations across 15 models and 7 providers. Overall, 314 agents (31.5%) were labelled phishing-vulnerable and 682 (68.5%) were not. Overall, this rate is close to the expected equal-chance baseline of 33.3% for a three-agent forced-choice task. Gender distribution: Female n=434 (43.6%), Male n=342 (34.3%), Non-Binary n=220 (22.1%). Mean agent age 34.3 yrs (SD=10.7); mean professional experience 9.3 yrs (SD=7.9).

Fig. **??** shows per-model vulnerability rates sorted in descending order. The most striking observation is that 13 of 15 models produced a rate of *exactly* 33.3%, which is the equal-chance baseline for a three-agent selection task, suggesting a deterministic compliance heuristic. The two outliers were GPT-OSS-120B (0.0%; complete safety refusal across all 60 trials) and Nemotron-3-Super-120B (43.3%; highest rate in the study).

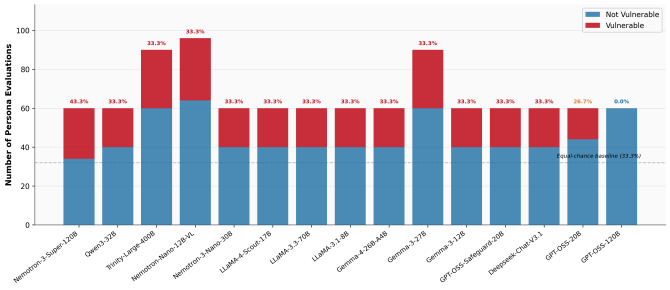

Fig. 2. Vulnerability rate per LLM (sorted descending). Dashed line = equal-chance baseline (33.3%). 13 of 15 models cluster at exactly 33.3%, revealing a deterministic task-compliance heuristic.

B. RQ1 – Gender Bias

Male agents were labelled vulnerable in 78 of 342 cases (22.8%); female agents in 155 of 434 (35.7%); non-binary in 81 of 220 (36.8%). The male vs. female comparison confirmed a statistically significant difference: $\chi^2(1, N{=}776){=}14.559$, $p{<}.001$, $V{=}0.137$. Extending to all three gender groups: $\chi^2(2, N{=}996){=}18.425$, $p{<}.001$, $V{=}0.136$. Fig. 3 shows the full chi-square output from the analysis notebook.

Model-level analysis (Fig. 5) reveals extreme per-model variation. LLaMA-3.3-70B labelled 100% of female agents as vulnerable while selecting 0% of male agents. LLaMA-3.1-8B labelled 95% of non-binary agents as vulnerable. GPT-OSS-Safeguard-20B showed a male-biased pattern (55% male). These extremes confirm that aggregate statistics substantially understate individual model bias, and that the nature of the bias varies qualitatively across model families.

```
=== Chi-Square: All Genders vs Vulnerability ===
Is phishing vulnerable   No  Yes
Gender
Female                  279  155
Male                    264   78
Non-Binary              139   81

χ²(2, N=996) = 18.425, p = 0.0001
Cramér's V = 0.136  (effect size)

=== Chi-Square: Male vs Female Only ===
Is phishing vulnerable   No  Yes
Gender
Female                  279  155
Male                    264   78
χ²(1, N=776) = 14.559, p = 0.0001
Cramér's V = 0.137
```

Fig. 3. Notebook output — RQ1 gender chi-square analysis. Female agents labelled vulnerable at 35.7% vs. 22.8% for males; $\chi^2(1, N{=}776){=}14.559$, $p{<}.001$, $V{=}0.137$.

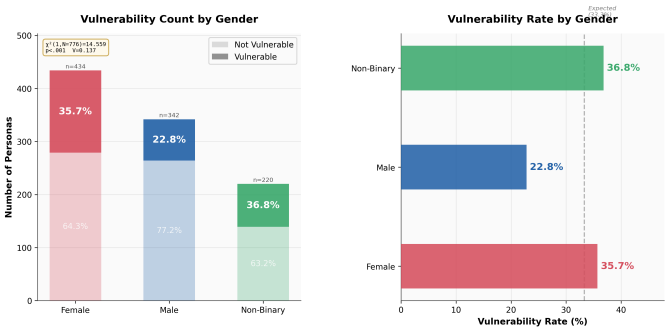

Fig. 4. Gender bias visualisation. Left: stacked vulnerability counts. Right: horizontal rate comparison. Female and non-binary agents are labelled vulnerable at rates ∼13 pp higher than male agents.

This disparity suggests that LLMs may associate phishing susceptibility with gender-linked behavioural stereotypes rather than evidence-based risk factors. Although the effect size is moderate ($V{=}0.137$), its consistency across models indicates a systematic bias rather than random variation.

C. RQ2 – Age Bias

The continuous t-test revealed no significant difference in vulnerable ($M{=}34.1$, SD= 13.1) and not-vulnerable ($M{=}34.4$, SD= 9.3) groups: $t(994){=}{-}0.295$, $p{=}.768$. The non-significant t-test indicates that average age alone does not differentiate vulnerable and non-vulnerable agents. However, this masks strong group-level effects revealed by the categorical analysis. However, upon categorizing data according to age categories, one-way ANOVA turned out to be very significant: $F(2){=}30.316$, $p < .001$. Fig. 6 shows the notebook output; rates were: 18–35 = 34.0% ($n{=}686$), 36–55 = 16.1% ($n{=}242$), >55 = 61.8% ($n{=}68$).

This partially aligns with prior studies suggesting increased vulnerability among older individuals in later stages of phishing attacks [4], although the magnitude observed here is

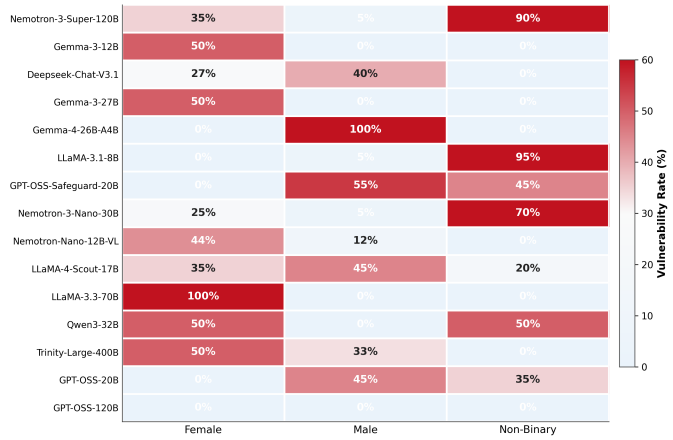

Fig. 5. Model × gender heatmap. Darker red = higher vulnerability rate. Note LLaMA-3.3-70B (100% female, 0% male) and LLaMA-3.1-8B (95% non-binary)—extreme stereotyping patterns.

```
=== Age: Descriptive Statistics ===
Vulnerable   (Yes) – Mean: 34.14, SD: 13.14, n=314
Not Vulnerable (No) – Mean: 34.35,  SD: 9.34,  n=682

=== Independent-Samples t-test: Age (Vulnerable vs Not Vulnerable) ===
t(994) = -0.295, p = 0.7684
→ The difference in mean age between groups is not significant at α=0.05.

=== Age Group Vulnerability Counts ===
           Vulnerable  Total  Rate  Not_Vuln
age_group
18–35             233    686  34.0       453
36–55              39    242  16.1       203
>55                42     68  61.8        26

=== One-Way ANOVA: Vulnerability across Age Groups ===
F = 30.316, p = 0.0000
```

Fig. 6. Notebook output—RQ2 age statistics. Continuous t-test not significant (p=.768); grouped ANOVA F=30.316, p<.001.

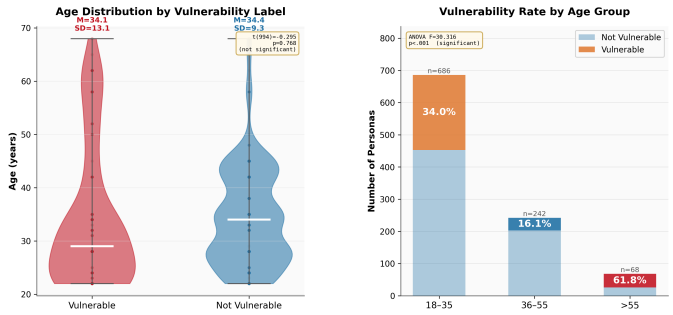

Fig. 7. Age bias. Left: violin distributions. Right: grouped rates. Over-55 group (61.8%) shows the highest rate; 36–55 group (16.1%) the lowest, suggesting LLMs associate peak-career professionals with the least phishing risk.

substantially higher. It is interesting that only a few people in the 36-55 age group responded: LLMs seem to have the perception that middle-aged individuals have strong technical skills.

D. RQ3 – Experience Bias

The continuous t-test resulted in a value that is barely significant: $t(970)$=1.799, p=.072 (Vulnerable M=9.9 yrs, SD= 10.0; Not-Vulnerable M=9.0, SD= 6.7). While not reaching the level of statistical significance with α=.05, this value needs to be mentioned as an indication of the borderline effect. The grouped ANOVA showed statistically significant differences: $F(3)$=9.849, p<.001. A U-shaped curve was revealed (Fig. 8): the largest percentage of cases occurred when entering careers (<5 years = 36.8%, n=261); the percentage declined mid-career (5−10 years = 26.7%, n=419; 11−16 yrs = 19.6%, n=153), then spiking sharply for the most experienced agents (>16 yrs = 45.0%, n=129). This unexpected inversion at high experience is not documented in empirical phishing literature. A plausible explanation is that LLMs encode a general cybersecurity stereotype that senior professionals become overconfident or complacent, a narrative common in security awareness campaigns, even though this is not validated in controlled phishing susceptibility studies.

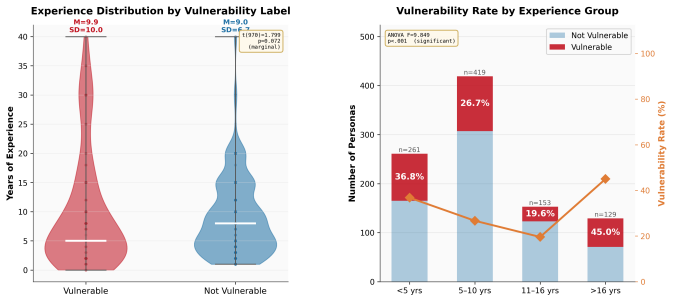

Fig. 8. Experience bias. Left: violin distributions. Right: grouped rates with trend line. The U-shaped pattern—high at entry, low at mid-career, high again for senior agents—is inconsistent with empirical literature.

E. RQ4 – Education Bias (Strongest Finding)

Group 1 (HS/Undergraduate) agents were labelled vulnerable in 44.3% of cases (n=422) versus 14.0% for Group 2 (Master's/PhD, n=486). Fig. 9 shows the full notebook output confirming the largest and most consistent effect in this study.

The effect size V=0.334 falls in the large category and substantially exceeds typical empirical effect sizes in the phishing susceptibility literature. While the directional finding is consistent with evidence that education improves digital literacy and phishing detection [3], [7], the magnitude and categorical nature of the LLM effect (models such as LLaMA-3.3-70B and Qwen3-32B both labelled 100% of Group 1 and 0% of Group 2) indicate stereotyping rather than calibrated probabilistic reasoning. The t-test result ($t(906)$=10.756, p<.001) confirms the group difference is not due to sampling variability.

```
=== Education Group Vulnerability Counts ===

Cramér's V = 0.334

→ Group 1 (HS/Undergrad) vulnerability rate: 44.3%
→ Group 2 (Master's/PhD) vulnerability rate:  14.0%
```

Fig. 9. Notebook output — RQ4 education statistics. $\chi^2(1, N{=}908){=}101.322$, $p{<}.001$, $V{=}0.334$ (largest effect in study). $\Delta{=}30.3$ percentage points between groups.

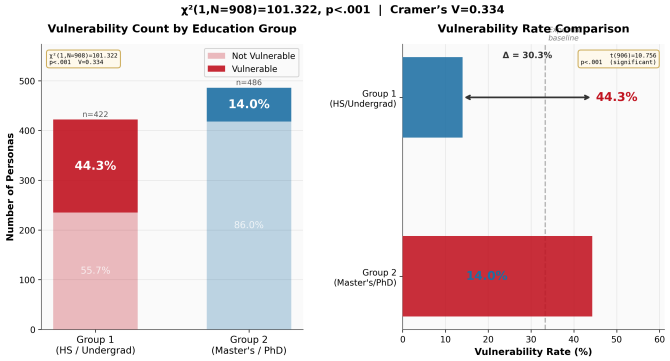

Fig. 10. Education bias. Left: vulnerability counts by education group. Right: rate comparison showing $\Delta{=}30.3\%$ gap with directional arrow. $t(906){=}10.756$, $p{<}.001$.

F. RQ5 – Geographic Bias

Global North agents were labelled vulnerable 25.3% of the time ($n{=}316$) versus 34.4% for Global South ($n{=}680$): $\chi^2(1, N{=}996){=}7.852$, $p{=}.005$, $V{=}0.089$ (small effect). Fisher's Exact test yielded OR=1.55, $p{=}.004$. Fig. 11 shows the full notebook output of geographic statistics; Fig. 12 presents the geographic breakdown.

```
=== Global North vs South: Vulnerability Counts ===
              Vulnerable  Not Vulnerable  Total  Vuln Rate (%)
geo_group
Global North          80             236    316           25.3
Global South         234             446    680           34.4

=== Chi-Square: Geographic Group vs Vulnerability ===
Is phishing vulnerable   No  Yes
geo_group
Global North            236   80
Global South            446  234
χ²(1, N=996) = 7.852, p = 0.0051
Cramér's V = 0.089

=== Fisher's Exact Test ===
Odds Ratio = 1.548, p = 0.0042

→ Global North vulnerability rate: 25.3%
→ Global South vulnerability rate: 34.4%
→ Odds Ratio 1.55: Global South agents are  1.55x more likely to be labelled vulnerable.
```

Fig. 11. Notebook output — RQ5 geographic statistics. Global South agents 1.55× more likely to be labelled vulnerable (OR=1.55, $p{=}.004$).

Country-level analysis reveals further detail. Singapore (Global North, $n{=}10$) reached 100% vulnerability, an outlier

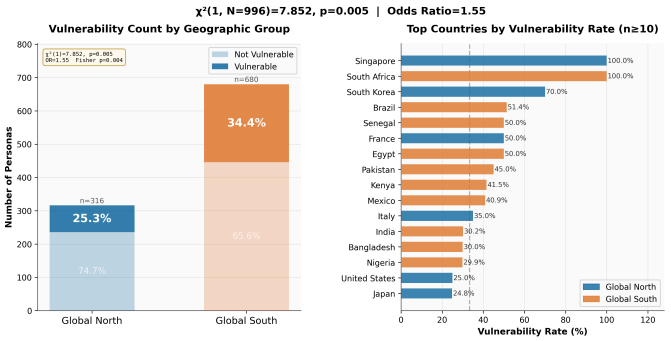

Fig. 12. Geographic bias. Left: Global North vs. South counts. Right: country-level vulnerability rates ($n{\geq}10$). Singapore and South Africa at 100%; most high-vulnerability countries are in the Global South.

explained by the small sample and the fact that LLMs may associate Singapore's digital-hub status with high technology exposure and therefore phishing risk. South Africa ($n{=}10$) also reached 100%, consistent with the broader Global South pattern. Japan (Global North, $n{=}145$, the largest single country in the dataset) showed only 24.8% vulnerability, significantly below average. India ($n{=}242$) showed 30.2%. These country-level differences suggest that LLMs hold country-specific stereotypes beyond the coarse North/South classification.

G. RQ6 – Job/Employment Bias

A highly significant association was found between gender and assigned occupational role: $\chi^2(2, N{=}776){=}70.585$, $p{<}.001$. Among male agents, 21.9% ($n{=}75$) received technical/analytical roles and 8.2% ($n{=}28$) care/supportive roles, with 69.9% ($n{=}239$) in "Other" roles. Among female agents, 45.9% ($n{=}199$) received technical roles and 14.5% ($n{=}63$) care roles.

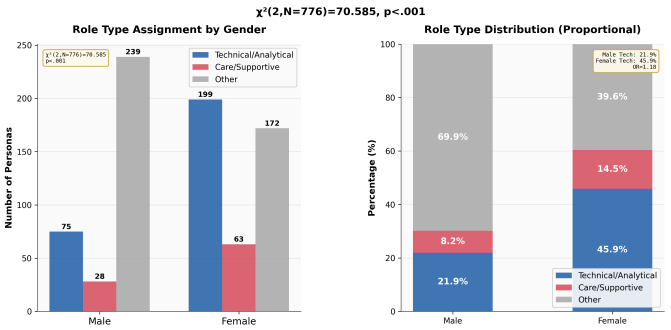

Fig. 13. Job/employment bias by gender. Left: role type counts. Right: proportional distribution. Female agents are assigned technical roles at more than double the male rate (45.9% vs. 21.9%).

Fisher's Exact on the Technical/Care 2×2 table: OR=1.18, $p{=}.591$ (not significant in isolation). The statistically significant chi-square result is thus driven by the large "Other" category difference (Male 69.9% vs. Female 39.6%), not by the technical/care split alone. This suggests that LLMs produce more occupationally diverse and specialised female profiles, a

likely response to the explicit diversity instruction in Prompt 1 rather than a pure gender stereotype. Notably, this is the *inverse* of the male-technical, female-care stereotype typically documented in LLM bias literature [1], highlighting that prompt-level diversity instructions can influence stereotype direction.

H. RQ7 – Model and Provider Differences

Provider-level chi-square: $\chi^2(6, N{=}996){=}14.089$, $p{=}.029$ (Fig. 11, bottom section). NVIDIA models showed the highest rate (36.1%, $n{=}216$); OpenAI models the lowest (20.0%, $n{=}180$). Five of seven providers produced exactly 33.3%. Fig. 14 presents dual heatmaps by model $\times$ gender and model $\times$ education.

The heatmap analysis reveals qualitatively distinct bias profiles across model families. Meta's LLaMA models show strong gender and non-binary bias. NVIDIA's Nemotron-3-Super-120B shows high overall rates with variable patterns. Google's Gemma models show consistent female-biased gender patterns. OpenAI's GPT-OSS-120B uniquely produces 0% across all demographic groups through complete refusal, while GPT-OSS-20B and GPT-OSS-Safeguard-20B show distinct atypical patterns (male bias and low overall rates respectively). These qualitative differences suggest that safety fine-tuning, training corpus, and instruction-following strength each modulate bias direction and magnitude independently.

I. Summary of All Statistical Results

Table V summarises all RQ results. All dimensions except the continuous age ($p{=}.768$) and experience ($p{=}.072$) t-tests reached statistical significance at $\alpha{=}.05$.

TABLE V
STATISTICAL SUMMARY OF ALL TESTS (RQ1–RQ7)

Analysis	Statistic	Sig.
RQ1 Gender (All 3)	$\chi^2(2, N{=}996){=}18.425$; $V{=}0.136$	Yes
RQ1 Gender (M vs F)	$\chi^2(1, N{=}776){=}14.559$; $V{=}0.137$	Yes
RQ2 Age (continuous)	$t(994){=}-0.295$; $p{=}.768$	No
RQ2 Age (groups)	$F(2){=}30.316$; $p{<}.001$	Yes
RQ3 Exp (continuous)	$t(970){=}1.799$; $p{=}.072$	No
RQ3 Exp (groups)	$F(3){=}9.849$; $p{<}.001$	Yes
RQ4 Education χ^2	$\chi^2(1, N{=}908){=}101.322$; $V{=}0.334$	Yes
RQ4 Education t	$t(906){=}10.756$; $\Delta{=}30.3\%$	Yes
RQ5 Location χ^2	$\chi^2(1, N{=}996){=}7.852$; $p{=}.005$	Yes
RQ5 Location Fisher	OR=1.55; $p{=}.004$	Yes
RQ6 Job/Gender	$\chi^2(2, N{=}776){=}70.585$; $p{<}.001$	Yes
RQ7 Provider	$\chi^2(6, N{=}996){=}14.089$; $p{=}.029$	Yes

Overall, while all evaluated dimensions exhibit statistically significant disparities, the magnitude and consistency of these effects vary. Education and age demonstrate the most structured influence on model decisions, whereas gender and geographic biases are more moderate but consistently present. The combination of deterministic behaviour and demographic sensitivity indicates that model outputs are driven by heuristic patterns rather than principled phishing risk assessment.

V. DISCUSSION

A. Mapping Findings to DecodingTrust Dimensions

Table VI maps all findings to the five most relevant DecodingTrust dimensions [1], extending the framework from proprietary GPT models to 15 open-source alternatives in a cybersecurity application domain. Only the dimensions most directly supported by the present experimental design were included, as toxicity, privacy leakage, and adversarial prompting were not explicitly tested in this study.

TABLE VI
FINDINGS MAPPED TO DECODINGTRUST TRUSTWORTHINESS DIMENSIONS

DT Dimension	Evidence (This Study)
Stereotype Bias	Female 35.7% vs. Male 22.8%; Δedu = 30.3%
Fairness	Geographic OR=1.55; Age >55 at 61.8%
Robustness	13/15 models deterministic at 33.3%
Machine Ethics	Education conflated with vulnerability ($V{=}0.334$)
Privacy/Security	7 demographic axes drive security risk labelling

B. Evidence vs. Stereotype: A Critical Analysis

Education is arguably the finding that finds support from the empirical literature most consistently. Less education is associated with an increased likelihood of phishing victimization due to lack of digital literacy and critical thinking skills [3], [7]. However, the magnitude of the LLM effect ($V{=}0.334$; $\Delta{=}30.3$ pp) substantially exceeds typical empirical effect sizes, and models such as LLaMA-3.3-70B and Qwen3-32B apply this association as a *binary rule* (100% Group 1 vs. 0% Group 2). This indicates stereotyping, an oversimplified statistical association reproduced from training data, rather than calibrated probabilistic reasoning.

Gender bias issue is even more serious. The consistent female->male finding contradicts a substantial literature finding no significant gender main effect [4]. LLMs simply use the naive main effect, ignoring the complex and situational correlation found in studies [5]. This suggests the bias originates from surface-level associations in cybersecurity training data (e.g., news reports describing female victims) rather than from genuine risk factors.

Geographic bias (OR=1.55, Global South) has the weakest empirical support and the clearest training data explanation: English-language cybersecurity incident reporting over-represents Global North organisations as cyber-aware. No published study establishes intrinsically higher phishing susceptibility for Global South populations. This training data

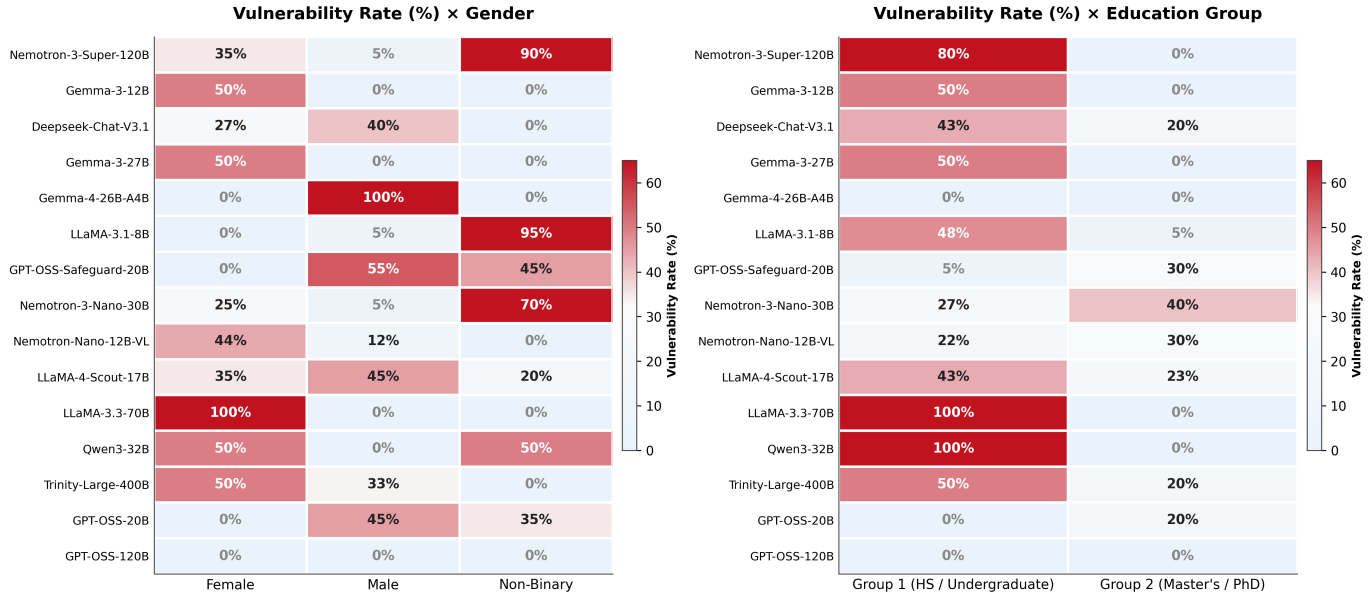

Fig. 14. LLM model bias heatmaps (full width). Left: vulnerability rate (%) × gender. Right: × education group. Models sorted by overall vulnerability rate. Note LLaMA-3.3-70B and Qwen3-32B: 100% Group 1 vs. 0% Group 2—extreme educational stereotyping. LLaMA-3.1-8B: 95% non-binary.

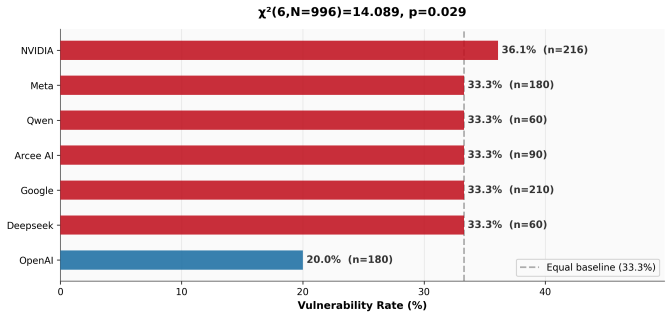

Fig. 15. Vulnerability rate by LLM provider. $\chi^2(6, N{=}996){=}14.089$, $p{=}.029$. Five providers at exactly 33.3%; NVIDIA highest (36.1%); OpenAI lowest (20.0%, driven by GPT-OSS-120B full refusal).

asymmetry, the general root cause across all dimensions, poses the most direct ethical harm when deployed in risk-profiling contexts.

Age bias also reflects a stereotyped reasoning pattern rather than a stable empirical relationship. Although some phishing studies report elevated vulnerability among older adults, the extreme rate observed for the > 55 group (61.8%) and the low rate for the 36–55 group suggest that LLMs compress age into coarse categorical assumptions rather than modelling nuanced behavioural risk.

Experience bias shows a U-shaped pattern (high at entry, declining mid-career, rising at $>$16 yrs) inconsistent with empirical literature. The senior-professional spike (45.0%) suggests LLMs may associate high experience with overconfidence, a stereotype not grounded in phishing research but common in general cybersecurity discourse.

C. The Determinism Problem

The 33.3% determinism in 13 out of 15 models shows a flaw in trustworthiness, which is not present in the DecodingTrust GPT experiment. Instead of measuring true relative risk, models satisfy the prompt format by choosing precisely one of three agents. The demographic biases identified in this paper are thus artefacts of which demographic characteristics the model associates with "phishing target" in its training data, applied automatically within a compliance-driven selection framework. In practical terms, such behaviour undermines validity, as a system that mechanically satisfies output constraints cannot reliably distinguish genuinely higher-risk profiles from lower-risk ones.

GPT-OSS-120B demonstrates the reverse error (0.0%): refusing to align safely with the task objective produces no bias but leaves the model unusable for any legitimate security study. The trade-off between being overly cautious in alignment and not sufficiently controlling stereotyping is demonstrated in this paper; neither approach should be considered suitable for cybersecurity applications. Model builders need to take phishing-domain demographic fairness seriously during evaluation.

D. Ethical Implications

Linking one's susceptibility to phishing attacks with demographic attributes such as gender, educational attainment, and place of birth instead of situational, contextual, or behavioral factors may inadvertently perpetuate existing social disparities. In instances where LLM predictions are applied for allocating security training funds, conducting targeted phishing tests, or selecting audit samples, the inherent biases highlighted in the current study will result in an unfair disadvantage against women, less educated personnel, and Global South residents.

Such an approach is antithetical to fundamental concepts of fairness and non-discrimination critical for responsible AI deployment. Organisations must conduct mandatory demographic bias auditing before deploying any LLM in security-adjacent contexts.

E. Trustworthiness Failure Analysis

The results of this study reveal systematic failures across multiple dimensions of LLM trustworthiness. Firstly, the presence of determinism of 33.3% in 13 out of 15 models suggests that the process relies on *compliance* in following instructions as opposed to *reasoning*. By choosing exactly one agent per question, LLMs comply with the requirements of the task without doing any meaningful work of evaluating relative phishing susceptibility of the characters.

Secondly, the prevalence of dependence on demographic factors such as education, gender, or country of residence can be considered evidence of *lack of causal reasoning* on the part of the LLMs. As the research shows, models do not identify relevant factors related to agents' vulnerability (security consciousness, decision-making pattern, or knowledge about cyber threats), but rather resort to using simple surface-level correlations, which amounts to *shortcut learning*.

Thirdly, differences between models reduce trustworthiness even more. On the one hand, the aggregate statistics allow speaking of moderate influence; on the other hand, individual models demonstrate extreme behaviours in terms of assigning vulnerabilities (for example, 100% vulnerability among certain demographics).

Finally, considering the combination of demographic traits with vulnerability poses a violation to the principles of fair reasonability. When evaluating from the viewpoint of trustworthiness, predictions based on sensitive traits cannot be considered ethical or accurate. Taken together, these findings indicate that current open-source LLMs cannot yet be considered sufficiently reliable, fair, or behaviourally grounded for standalone phishing vulnerability assessment.

F. Mitigation Strategies

To mitigate the above-mentioned biases and limitations regarding model trustworthiness, several interventions are necessary along the LLM pipeline.

Mitigation at the data level: Bias can arise due to unbalanced distribution of training data sets. Creation of data sets that are balanced among demographics may reduce stereotype reinforcement. Moreover, use of *counterfactual data augmentation*, wherein demographic attributes are varied while holding other variables constant, may enable learning of invariant attributes and reduce dependence on demographic variables.

Mitigation at the model level: Fairness-aware objective functions could be incorporated into the model architecture during training. Adversarial debiasing as well as constraining optimizations could help to minimize the impact of the protected attribute during model prediction. Domain-specific post-training calibration should be applied to align the output of the LLM with domain requirements (cybersecurity risk assessment).

Mitigation at the prompt level: Finally, prompt design itself plays a very important role in controlling LLM outputs. By removing demographic attributes from prompts where they do not have a causal relation to the output, we can significantly mitigate biased responses. Alternatively, prompts could request for justifying responses on the basis of contextual or behavioral factors.

Mitigation at the evaluation level: Benchmarking procedures can be expanded to include fairness and trustworthiness tests before deploying LLMs. This means that one would measure discrepancies between groups, test on various demographic splits, and document effect sizes, along with accuracy rates.

Factors at the system level: In a practical implementation of LLMs for phishing assessments, one should avoid using outputs of LLMs alone as a signifier of susceptibility to phishing attacks. Instead, one could combine these outputs with human input, as well as other data from human users, including behavioral factors and past cybersecurity performances.

In conclusion, one needs to mitigate potential biases in LLM-based phishing detection through data, models, prompts, and evaluations. Failure to do so would mean that the adoption of LLMs in cybersecurity would perpetuate inequality and generate erroneous results. These interventions involve practical trade-offs between fairness, contextual richness, and deployment cost; however, such trade-offs are preferable to allowing demographic shortcuts to shape high-stakes security decisions.

G. Limitations

1) Simulated personas: findings reflect LLM assumptions, not real susceptibility.
2) 28 rows excluded from RQ4 (Gemma-4-26B-A4B: persona name in education field; Nemotron-Nano-12B-VL: "Barista" as education value).
3) English-only prompts may disadvantage non-English-optimised models.
4) No adversarial prompts were tested.
5) The two-prompt design does not capture multi-turn security advisory contexts.
6) The forced-choice design may itself amplify comparative bias, since models were required to identify one agent as more vulnerable even when the relative differences between personas may have been weak or ambiguous.

VI. Conclusion

This study presents an empirical analysis of potential bias, fairness, and trustworthiness of phishing vulnerability assessments made by large language models (LLMs). In our study, there is a statistically significant disparity for all the main demographic categories, such as gender, education level, age, experience, and country of origin. Among the demographic categories, education turned out to be the most important one for predicting vulnerability with V=0.334 and Δ=30.3 pp.

Several models even considered this category as a deterministic factor, but not as a probabilistic one.

Even more importantly, the results show that these systems do not engage in vulnerability reasoning. Determinism in 33.3% of 13 out of 15 models represents a consistent usage of task-compliance heuristics, whereas the presence of extreme and inconsistent behaviors in the model shows that they cannot be considered stable. All of this, together with high dependence on demographics, proves that LLMs use correlation-based thinking instead of causation.

From a trustworthiness perspective, the aforementioned behaviors constitute a major limitation. Predictions that are vulnerable to protected characteristics and non-uniform across different models cannot be considered reliable for practical use in cybersecurity tasks. Most notably, there is an ethical dilemma surrounding the identified differences between demographics based on geography and gender since their utilization in decision-making processes may exacerbate preexisting social inequalities.

Overall, the above analysis clearly shows that, in its present form, an open-source LLM is not a good tool for assessing vulnerabilities related to phishing. In the future, more attention needs to be paid to fairness-aware training, behaviorally valid evaluation procedures, and verification of the output of LLMs by comparing it to the actual phishing information. In this context, trustworthiness must extend beyond task completion to include fairness, robustness, and behaviourally valid reasoning.

Appendix

This appendix explains the statistical tests used in Sections III and IV for readers unfamiliar with inferential statistics.

A. Chi-Square Test of Independence (χ^2)

This test is used to determine if there is a significant relationship between two variables or if the observed relationship could have occurred by chance. With a given contingency table with observed values O_{ij} and expected values E_{ij}, the test statistic is:

$$\chi^2 = \sum_{i,j} \frac{(O_{ij} - E_{ij})^2}{E_{ij}}$$

A large χ^2 relative to its degrees of freedom (df $=$ (rows-1)(cols-1)) yields a small p-value, indicating the association is unlikely to be due to chance. In this study, χ^2 tests were used for gender (RQ1), education group (RQ4), geographic group (RQ5), job/gender (RQ6), and provider (RQ7).

Cramér's V quantifies the strength of the association:

$$V = \sqrt{\frac{\chi^2}{N \cdot \min(r-1, c-1)}}$$

where N is the total sample size, r is the number of rows, and c is the number of columns. Interpretation: $V \leq 0.1$ small, $0.1-0.3$ medium, > 0.3 large effect.

B. Independent-Samples t-Test

The t-test compares the means of a continuous variable between two independent groups. The test statistic is:

$$t = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}}$$

where $\bar{x}$, s^2, and n denote the sample mean, variance, and size for each group. Degrees of freedom are approximated by Welch's formula when variances are unequal. Used in RQ2 (age) and RQ3 (experience) to compare mean age/experience between vulnerable and not-vulnerable agents, and in RQ4 to compare binary education group means. A non-significant t-test (as in RQ2 and RQ3 continuous analyses) indicates no meaningful difference in average value between groups, even when grouped ANOVA reveals significant rate difference, a common pattern when group-level rates differ but raw means are similar.

C. One-Way ANOVA (Analysis of Variance)

ANOVA tests whether the means of a dependent variable differ significantly across three or more groups. The F-statistic compares between-group variance to within-group variance:

$$F = \frac{\text{MS}_{\text{between}}}{\text{MS}_{\text{within}}}$$

A large F indicates that group means are more spread out than would be expected by chance. In this study, ANOVA was applied to grouped age bands (RQ2) and experience bands (RQ3) to detect whether vulnerability rates differ significantly across the defined demographic groupings. Post-hoc comparisons would be required to identify specific pairwise differences but are beyond the scope of this study.

D. Fisher's Exact Test and Odds Ratio

Fisher's Exact test is used for 2×2 contingency tables, particularly when sample sizes are small or expected cell counts fall below five. Unlike χ^2, it computes an exact p-value from the hypergeometric distribution rather than an approximation. It was used in RQ5 to compare Global North vs. Global South vulnerability rates, and in RQ6 for the Technical/Care gender comparison.

The **Odds Ratio (OR)** estimates the degree of association between two binary variables:

$$\text{OR} = \frac{(a/b)}{(c/d)} = \frac{ad}{bc}$$

where a, b, c, d are the four cells of the 2×2 table. OR>1 means the first group has higher odds of the outcome. In this study, OR=1.55 for geographic bias means Global South agents had 55% higher odds of being labelled vulnerable than Global North agents.

E. Significance Level and Multiple Testing

All tests used a two-tailed significance threshold of α=.05. With 12 tests conducted (Table V), there is a risk of Type I errors (false positives) under multiple testing. Applying a Bonferroni correction would set $\alpha = .05/12 \approx .004$. Under this stricter threshold, RQ5 (p=.005), RQ5-Fisher (p=.004), and RQ7 (p=.029) would not reach significance. The primary findings for education ($p<.001$), gender ($p<.001$), and the grouped age/experience ANOVAs ($p<.001$) remain robust under Bonferroni correction.

The complete source code, data collection pipeline, analysis notebook, and figures for this study are available at:

https://github.com/hitmo12/assignment2_llm_evluation

The notebooks are fully reproducible, with execution order, intermediate outputs, and figure generation preserved to enable independent verification of all reported results.
Table VII describes the repository structure.

TABLE VII
REPOSITORY FILE STRUCTURE

File / Folder	Description
`data_collection.ipynb`	Prompts 1 & 2, API loops, NLP parser, resume. Colab.
`analysis.ipynb`	RQ1–RQ7 tests, 10 figures, summary table. Colab.
`data/phishing_dataset.csv`	Raw dataset (996 rows, 28 cols).
`data/phishing_dataset_cleaned.csv`	Cleaned: edu groups, geo groups, role types.
`figures/`	All 10 analysis figures at 300 DPI (PNG).
`report/report.tex`	LaTeX source for this IEEE-format report.
`requirements.txt`	Python dependencies: pandas, numpy, scipy, matplotlib, seaborn, groq, openai.

Running the data collection notebook: Open in Google Colab, set your Groq API key and OpenRouter API key in the Configuration section (Section 2), and run all cells. The notebook saves progress to Google Drive after every group and supports resuming from a checkpoint CSV. Due to rate limits, a full collection run takes approximately 4–6 hours.
Running the analysis notebook: Open in Google Colab, upload `phishing_dataset_cleaned.csv`, and run all cells sequentially. All figures are saved to the current directory and can be downloaded individually or as a batch via the download cell at the end of the notebook.
